An introduction to social network analysis with **Pajek** is available in the book **ESNA 3** (de Nooy, Mrvar, Batagelj, CUP 2005, 2011, 2018).

ESNA in Japanese was published by Tokyo Denki University Press in 2010; and in Chinese by Beijing World Publishing in November 2012.

Pajek – program for analysis and visualization of large networks is freely available, for noncommercial use, at its web site.

A **network** is based on two sets – set of **nodes** (vertices), that represent the selected **units**, and set of **links** (lines), that represent **ties** between units. They determine a **graph**. A link can be **directed** – an **arc**, or **undirected** – an **edge**.

Additional data about nodes or links can be known – their **properties** (attributes). For example: name/label, type, value, ...

Network = Graph + Data

The data can be measured or computed.

A **network** $\mathbf{N} = (\mathcal{V}, \mathcal{L}, \mathcal{P}, \mathcal{W})$ consists of:

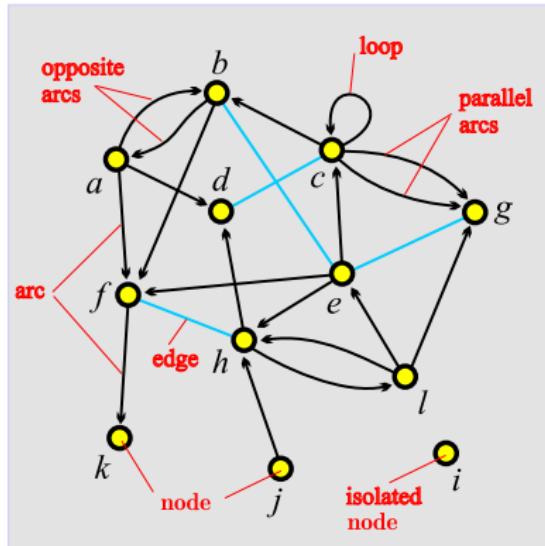

- a **graph** $\mathcal{G} = (\mathcal{V}, \mathcal{L})$, where \mathcal{V} is the set of nodes, \mathcal{A} is the set of arcs, \mathcal{E} is the set of edges, and $\mathcal{L} = \mathcal{E} \cup \mathcal{A}$ is the set of links.
 $n = |\mathcal{V}|$, $m = |\mathcal{L}|$
- \mathcal{P} **node value functions** / properties: $p: \mathcal{V} \rightarrow A$
- \mathcal{W} **link value functions** / weights: $w: \mathcal{L} \rightarrow B$

Node Properties / CLU, VEC, PER

All three types of files have the same structure:

*vertices n

n is the number of nodes

v_1

node 1 has value v_1

...

v_n

CLUstering – partition of nodes – *nominal* or *ordinal* data about nodes

$v_i \in \mathbb{N}$: node i belongs to the cluster/group v_i ;

VEctor – *numeric* data about nodes

$v_i \in \mathbb{R}$: the property has value v_i on node i ;

PERmutation – *ordering* of nodes

$v_i \in \mathbb{N}$: node i is at the v_i -th position.

When collecting the network data consider to provide as much properties as possible.

Pajek's Project File / PAJ

All types of data can be combined into a single file – Pajek's **project** file *file.paj*.

The easiest way to do this is:

- read all data files in Pajek,
- compute some additional data,
- delete (dispose) some data,
- save all as a project file with
File/Pajek Project File/Save.

Next time you can restore everything with a single
File/Pajek Project File/Read.

Wolfe network as a (**Pajek's project file**).

Representations of properties

Properties of nodes \mathcal{P} and links \mathcal{W} can be measured in different scales: numerical, ordinal and nominal. They can be *input* as data or *computed* from the network.

In **Pajek** numerical properties of nodes are represented by *vectors*, nominal properties by *partitions* or as *labels* of nodes. Numerical property can be displayed as *size* (width and height) of node (figure), as its *coordinate*; and a nominal property as *color* or *shape* of the figure, or as a node's *label* (content, size and color).

We can assign in **Pajek** numerical values to links. They can be displayed as *value*, *thickness* or *grey level*. Nominal values can be assigned as *label*, *color* or *line pattern* (see **Pajek manual**, section **4.3**).

Types of networks

Besides ordinary (directed, undirected, mixed) networks some extended types of networks are also used:

- ***2-mode networks***, bipartite (valued) graphs – networks between two disjoint sets of nodes $\mathbf{N} = ((\mathcal{U}, \mathcal{V}), \mathcal{L}, \mathcal{P}, \mathcal{W})$
- ***multi-relational networks*** $\mathbf{N} = (\mathcal{V}, (\mathcal{L}_1, \mathcal{L}_2, \dots, \mathcal{L}_k), \mathcal{P}, \mathcal{W})$
- ***temporal networks***, dynamic graphs – networks changing over time $\mathbf{N}_T = (\mathcal{V}, \mathcal{L}, \mathcal{P}, \mathcal{W}, T)$
- specialized networks: representation of genealogies as ***p-graphs***; ***Petri's nets***, ...

The network (input) file formats should provide means to express all these types of networks. All interesting data should be recorded (respecting privacy).

Pictures in SVG: **66 days**.

Let's describe in Pajek format the network in picture wNet21.jpeg. First we number the nodes (vertices)

Then we prepare the NET file `oilTrade.net`. Two arcs are without value - we guess it from the arc's thickness.

We read the network in Pajek and draw it Draw/Network. Manually move the nodes to the "right" places. Set the thickness on [Draw]Options/Lines/Different widths. Set the size of links [Draw]Options/Size/Of lines [1] and the size of arrows [Draw]Options/Size/Of arrows [3]. Export the picture. Save the network with picture coordinates File/Network/Save [oilTradeXY.net].

Important nodes and links in network

Analysis of
weighted
networks

V. Batagelj

Introduction

Networks

Properties

Statistics

Connectivity

Important
subnetworks

References

To identify important / interesting elements (nodes, links) in a network we often try to express our intuition about important / interesting elements using an appropriate measure (index, weight) following the scheme

*larger is the measured value of an element,
more important / interesting is this element*

Too often, in the analysis of networks, researchers uncritically pick some measures from the literature. For a formal approach see **Roberts**.

The (importance) measure can be obtained as input data – an **observed** property, or computed from the network description – a **structural** property.

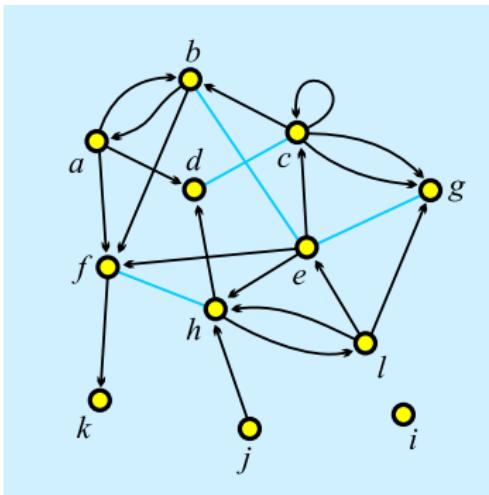

An interesting question is studying associations among structural and observed properties. Can an observed property be explained with some structural property/ies?

Degrees

Analysis of
weighted networks

V. Batagelj

Introduction
Networks
Properties
Statistics
Connectivity
Important subnetworks
References

degree of node v , $\deg(v)$ = number of links with v as an endnode;

indegree of node v , $\text{indeg}(v)$ = number of links with v as a terminal node (endnode is both initial and terminal);

outdegree of node v , $\text{outdeg}(v)$ = number of links with v as an initial node.

initial node $v \Leftrightarrow \text{indeg}(v) = 0$

terminal node $v \Leftrightarrow \text{outdeg}(v) = 0$

$$n = 12, m = 23, \text{indeg}(e) = 3, \text{outdeg}(e) = 5, \deg(e) = 6$$

$$\sum_{v \in \mathcal{V}} \text{indeg}(v) = \sum_{v \in \mathcal{V}} \text{outdeg}(v) = |\mathcal{A}| + 2|\mathcal{E}| - |\mathcal{E}_0|, \sum_{v \in \mathcal{V}} \deg(v) = 2|\mathcal{L}| - |\mathcal{L}_0|$$

Node indices

The most important distinction between different node *indices* is based on the view/decision of whether the network is considered directed or undirected.

Closeness, betweenness, clustering, eigen-vector, ...

Weighted degree, indegree and outdegree

$$\text{wdeg}(v) = \sum_{e \in \text{star}(v)} w(e),$$

$$\text{windeg}(v) = \sum_{e \in \text{instar}(v)} w(e) \quad \text{and} \quad \text{woutdeg}(v) = \sum_{e \in \text{outstar}(v)} w(e)$$

Hubs and authorities

To each node v of a network $\mathbf{N} = (\mathcal{V}, \mathcal{L})$ we assign two values: quality of its content (*authority*) x_v and quality of its references (*hub*) y_v .

A good authority is selected by good hubs; and good hub points to good authorities (see [Kleinberg](#)).

$$x_v = \sum_{u:(u,v) \in \mathcal{L}} y_u \quad \text{and} \quad y_v = \sum_{u:(v,u) \in \mathcal{L}} x_u$$

Let \mathbf{W} be a matrix of network \mathbf{N} and \mathbf{x} and \mathbf{y} authority and hub vectors. Then we can write these two relations as $\mathbf{x} = \mathbf{W}^T \mathbf{y}$ and $\mathbf{y} = \mathbf{W} \mathbf{x}$.

We start with $\mathbf{y} = [1, 1, \dots, 1]$ and then compute new vectors \mathbf{x} and \mathbf{y} . After each step we normalize both vectors. We repeat this until they stabilize.

We can show that this procedure converges. The limit vector \mathbf{x}^* is the principal eigen vector of matrix $\mathbf{W}^T \mathbf{W}$; and \mathbf{y}^* of matrix $\mathbf{W} \mathbf{W}^T$.

Important links – Weighted networks

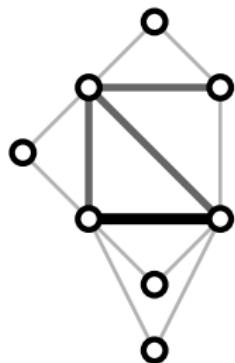

A very important characteristic of weight is its nature – should it be considered a *similarity* (larger is the link weight more similar are its end-nodes) or a *dissimilarity* (larger is the link weight more different are its end-nodes; weight for links with equal end-nodes is usually 0)?

Structural weights are computed based on network structure. For example

$$w(e(u, v)) = \deg(u) \cdot \deg(v)$$

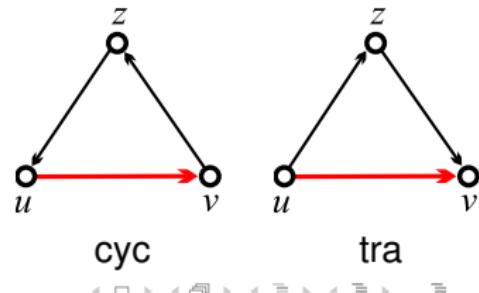

More substantial weights exist.

Triangular network

Let \mathbf{G} be a simple undirected graph. A *triangular network* $\mathbf{N}_T(\mathbf{G}) = (\mathcal{V}, \mathcal{E}_T, w)$ determined by \mathbf{G} is a subgraph $\mathbf{G}_T = (\mathcal{V}, \mathcal{E}_T)$ of \mathbf{G} whose set of edges \mathcal{E}_T consists of all triangular edges of $\mathcal{E}(\mathbf{G})$. For $e \in \mathcal{E}_T$ the weight $w(e)$ equals to the number of different triangles in \mathbf{G} to which e belongs. Triangular networks can be used to efficiently identify dense clique-like parts of a graph. If an edge e belongs to a k -clique in \mathbf{G} then $w(e) \geq k - 2$.

If a graph \mathbf{G} is mixed we replace edges with pairs of opposite arcs. Let $\mathbf{G} = (\mathcal{V}, \mathcal{A})$ be a simple directed graph without loops. For a selected arc $(u, v) \in \mathcal{A}$ there are only two different types of directed triangles: **cyclic** and **transitive**.

Multiplication of networks

To a simple (no parallel arcs) two-mode **network** $\mathbf{N} = (\mathcal{I}, \mathcal{J}, \mathcal{A}, w)$; where \mathcal{I} and \mathcal{J} are sets of **nodes**, \mathcal{A} is a set of **arcs** linking \mathcal{I} and \mathcal{J} , and $w : \mathcal{A} \rightarrow \mathbb{R}$ (or some other semiring) is a **weight**; we can assign a **network matrix** $\mathbf{W} = [w_{i,j}]$ with elements: $w_{i,j} = w(i,j)$ for $(i,j) \in \mathcal{A}$ and $w_{i,j} = 0$ otherwise.

Given a pair of compatible networks $\mathbf{N}_A = (\mathcal{I}, \mathcal{K}, \mathcal{A}_A, w_A)$ and $\mathbf{N}_B = (\mathcal{K}, \mathcal{J}, \mathcal{A}_B, w_B)$ with corresponding matrices $\mathbf{A}_{\mathcal{I} \times \mathcal{K}}$ and $\mathbf{B}_{\mathcal{K} \times \mathcal{J}}$ we call a **product of networks** \mathbf{N}_A and \mathbf{N}_B a network $\mathbf{N}_C = (\mathcal{I}, \mathcal{J}, \mathcal{A}_C, w_C)$, where $\mathcal{A}_C = \{(i,j) : i \in \mathcal{I}, j \in \mathcal{J}, c_{i,j} \neq 0\}$ and $w_C(i,j) = c_{i,j}$ for $(i,j) \in \mathcal{A}_C$. The product matrix $\mathbf{C} = [c_{i,j}]_{\mathcal{I} \times \mathcal{J}} = \mathbf{A} * \mathbf{B}$ is defined in the standard way

$$c_{i,j} = \sum_{k \in \mathcal{K}} a_{i,k} \cdot b_{k,j}$$

In the case when $\mathcal{I} = \mathcal{K} = \mathcal{J}$ we are dealing with ordinary one-mode networks (with square matrices).

Multiplication of networks

Analysis of
weighted networks

V. Batagelj

Introduction

Networks

Properties

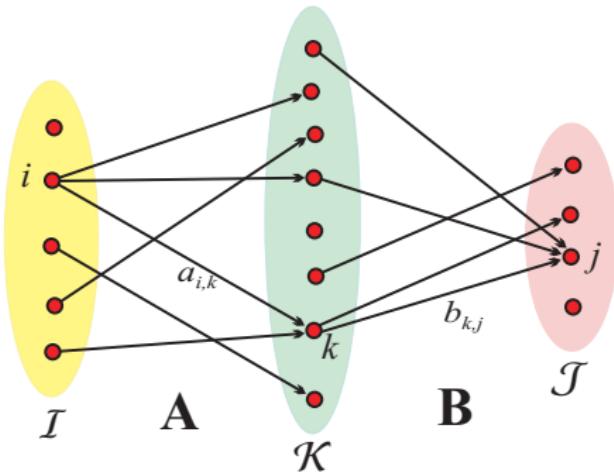

Statistics

Connectivity

Important

subnetworks

References

$$c_{i,j} = \sum_{k \in N_A(i) \cap N_B^-(j)} a_{i,k} \cdot b_{k,j}$$

If all weights in networks \mathbf{N}_A and \mathbf{N}_B are equal to 1 the value of $c_{i,j}$ counts the number of ways we can go from $i \in \mathcal{I}$ to $j \in \mathcal{J}$ passing through \mathcal{K} , $c_{i,j} = |N_A(i) \cap N_B^-(j)|$.

Multiplication of networks

The standard matrix multiplication has the complexity $O(|\mathcal{I}| \cdot |\mathcal{K}| \cdot |\mathcal{J}|)$ – it is too slow to be used for large networks. For sparse large networks we can multiply much faster considering only nonzero elements.

```
for k in K do
    for (i,j) in N_A^-(k) × N_B(k) do
        if ∃ c_{i,j} then c_{i,j} := c_{i,j} + a_{i,k} · b_{k,j}
        else new c_{i,j} := a_{i,k} · b_{k,j}
```

Networks/Multiply Networks

In general the multiplication of large sparse networks is a 'dangerous' operation since the result can 'explode' – it is not sparse.

Multiplication of networks

From the network multiplication algorithm we see that each intermediate node $k \in \mathcal{K}$ adds to a product network a complete two-mode subgraph $K_{N_A^-(k), N_B(k)}$ (or, in the case $\mathcal{I} = \mathcal{J}$, a complete subgraph $K_{N(k)}$). If both degrees $\deg_A(k) = |N_A^-(k)|$ and $\deg_B(k) = |N_B(k)|$ are large then already the computation of this complete subgraph has a quadratic (time and space) complexity – the result 'explodes'.

If at least one of the sparse networks \mathbf{N}_A and \mathbf{N}_B has small maximal degree on \mathcal{K} then also the resulting product network \mathbf{N}_C is sparse.

If for the sparse networks \mathbf{N}_A and \mathbf{N}_B there are in \mathcal{K} only few nodes with large degree and no one among them with large degree in both networks then also the resulting product network \mathbf{N}_C is sparse.

Projections of two-mode networks

Often we transform a two-mode network $\mathbf{N} = (\mathcal{U}, \mathcal{V}, \mathcal{E}, w)$ into an ordinary (one-mode) network $\mathbf{N}_1 = (\mathcal{U}, \mathcal{E}_1, w_1)$ or/and

$\mathbf{N}_2 = (\mathcal{V}, \mathcal{E}_2, w_2)$, where \mathcal{E}_1 and w_1 are determined by the matrix $\mathbf{W}^{(1)} = \mathbf{W}\mathbf{W}^T$,

$$w_{uv}^{(1)} = \sum_{z \in \mathcal{V}} w_{uz} \cdot w_{zv}^T = \sum_{z \in \mathcal{V}} w_{uz} \cdot w_{vz}.$$

Evidently $w_{uv}^{(1)} = w_{vu}^{(1)}$. There is an edge $(u : v) \in \mathcal{E}_1$ in \mathbf{N}_1 iff $N(u) \cap N(v) \neq \emptyset$. Its weight is $w_1(u, v) = w_{uv}^{(1)}$.

The network \mathbf{N}_2 is determined in a similar way by the matrix $\mathbf{W}^{(2)} = \mathbf{W}^T\mathbf{W}$.

The networks \mathbf{N}_1 and \mathbf{N}_2 are analyzed using standard methods.

Network/2-Mode Network/2-Mode to 1-Mode/Rows

Derived networks

WA – works \times authors – authorship network

WK – works \times keywords

Ci – works \times works – citation network

AK = **WA**^T * **WK** – authors \times keywords

Co = **WA**^T * **WA** – coauthorship

ACi = **WA**^T * **Ci** * **WA** – citations between authors

co_{ij} = the number of works that authors i and j wrote together

It holds: $co_{ij} = co_{ji}$. Using the weights co_{ij} we can determine the Salton's cosine similarity or Ochiai coefficient between authors i and j as

$$S(i, j) = \cos(i, j) = \frac{co_{ij}}{\sqrt{co_{ii}co_{jj}}}$$

Properties of Salton index

The Salton index has the following properties

- ① $S(i, j) \in [-1, 1]$
- ② $S(i, j) = S(j, i)$
- ③ $S(i, i) = 1$
- ④ $wa_{pi} \in \mathbb{R}_0^+ \Rightarrow S(u, t) \in [0, 1]$
- ⑤ $S(\alpha i, \beta j) = S(i, j), \quad \alpha, \beta > 0$
- ⑥ $S(\alpha i, i) = 1, \quad \alpha > 0$

Normalizations

In networks obtained from large two-mode networks, there are often huge differences in weights. Therefore it is not interesting to compare the nodes according to the raw data – the nodes with large weights will prevail. First, we have to *normalize* the network to make the weights comparable.

There exist several ways how to do this. Some of them are presented in the following. They can be used also on other weighted networks. Often a given weighted network is essentially a projection of a two-mode network; sometimes without loops. Assume that the network is described with a square matrix \mathbf{C} .

Let us denote the row sum $R(u) = \sum_{v \in V} c[u, v]$, which is the total of weights from node u to other nodes. Let $C(v) = \sum_{u \in V} c[u, v]$ denote the column sum for the node v . If the network is a projection of a two-mode network we set $R(u) = C(u) = c[u, u]$.

... Normalizations

Markov (also known as stochastic, affinity, output, row) normalization: For $R(u) > 0$

$$c_M[u, v] = \frac{c[u, v]}{R(u)}$$

If $R(u) = 0$ also $c_M[u, v] = 0$.

Jaccard-like normalization:

$$c_J[u, v] = \frac{c[u, v]}{R(u) + R(v) - c[u, v]}$$

Salton-like normalization:

$$c_S[u, v] = \frac{c[u, v]}{\sqrt{R(u) \cdot R(v)}}$$

... Normalizations

Balassa or activity normalization: Let $T = \sum_{u,v} c[u, v]$ be the total sum of weights in the network.

$$A[u, v] = \frac{c[u, v] \cdot T}{R(u) \cdot C(v)}$$

If $A[u, v] > 1$ the measured weight is larger than expected.

$$c_B[u, v] = \log_2 A[u, v] \quad \text{for } A[u, v] > 0$$

... Normalizations

$$c_{\min}[u, v] = \frac{c[u, v]}{\min(R(u), R(v))} \quad c_{\max}[u, v] = \frac{c_{uv}}{\max(c_{uu}, c_{vv})}$$

$$c_{\min\text{Dir}}[u, v] = \begin{cases} \frac{c[u, v]}{R(u)} & R(u) \leq R(v) \\ 0 & \text{otherwise} \end{cases}$$

$$c_{\max\text{Dir}}[u, v] = \begin{cases} \frac{c[u, v]}{R(v)} & R(u) \leq R(v) \\ 0 & \text{otherwise} \end{cases}$$

After a selected normalization the important parts of the network are obtained by link-cuts or islands approaches.

Normalized co-authorship network

Let \mathbf{N} be the normalized version $\forall p \in W : \sum_{i \in A} n_{pi} \in \{0, 1\}$ obtained from \mathbf{WA} by $n_{pi} = wa_{pi} / \max(1, \text{outdeg}_{\mathbf{WA}}(p))$, or by some other rule determining the author's contribution – the *fractional* approach. Then the *normalized co-authorship network* is

$$\mathbf{Cn} = \mathbf{N}^T \cdot \mathbf{N}$$

$cn_{ij} =$ the total contribution of ‘collaboration’ of authors i and j to works.

It holds $cn_{ij} = cn_{ji}$ and $\sum_{i \in A} \sum_{j \in A} n_{pi} n_{pj} = 1$.

The total contribution of a complete subgraph corresponding to the authors of a work p is 1.

$$\sum_{i \in A} \sum_{j \in A} cn_{ij} = |W|$$

Newman defined a *strict normalization* \mathbf{N}' obtained from \mathbf{WA} by $n'_{pi} = wa_{pi} / \max(1, \text{outdeg}_{\mathbf{WA}}(p) - 1)$. Then the *normalized strict co-authorship network* is

$$\mathbf{Cn}' = \mathbf{N}'^T \cdot \mathbf{N}'$$

The diagonal (loops) of the so-obtained network \mathbf{Cn}' is set to 0.

The network \mathbf{Cn}' doesn't consider the contribution of single-author works.

Size of network

The size of a network/graph is expressed by two numbers:
number of nodes $n = |\mathcal{V}|$ and number of links $m = |\mathcal{L}|$.

In a *simple undirected* graph (no parallel edges, no loops)
 $m \leq \frac{1}{2}n(n - 1)$; and in a *simple directed* graph (no parallel arcs)
 $m \leq n^2$.

Small networks (some tens of nodes) – can be represented by a picture and analyzed by many algorithms (**UCINET**, **NetMiner**).

Also, *middle size* networks (some hundreds of nodes) can still be represented by a picture (!?), but some analytical procedures can't be used.

Till 1990 most networks were small – they were collected by researchers using surveys, observations, archival records, ... The advances in IT allowed to create networks from the data already available in the computer(s). *Large* networks became reality. Large networks are too big to be displayed in detail; special

Large networks

Large network – several thousands or millions of nodes. Can be stored in the computer's memory – otherwise **huge** network. 64-bit computers!

Dunbar's number

Average degrees of the SNAP and Konect networks

Average degree $\bar{d} = \frac{1}{n} \sum_{v \in V} \deg(v) = \frac{2m}{n}$. Most real-life large networks are **sparse** – the number of nodes and links are of the same order. This property is also known as a **Dunbar's number**.

The basic idea is that if each node has to spend for each link a certain amount of "energy" to maintain the links to selected other nodes then since it has a limited "energy" at its disposal, the number of links should be limited. In human networks, Dunbar's number is between 100 and 150.

Complexity of algorithms

Let us look to time complexities of some typical algorithms:

	T(n)	1.000	10.000	100.000	1.000.000	10.000.000
LinAlg	$O(n)$	0.00 s	0.015 s	0.17 s	2.22 s	22.2 s
LogAlg	$O(n \log n)$	0.00 s	0.06 s	0.98 s	14.4 s	2.8 m
SqrtAlg	$O(n\sqrt{n})$	0.01 s	0.32 s	10.0 s	5.27 m	2.78 h
SqrAlg	$O(n^2)$	0.07 s	7.50 s	12.5 m	20.8 h	86.8 d
CubAlg	$O(n^3)$	0.10 s	1.67 m	1.16 d	3.17 y	3.17 ky

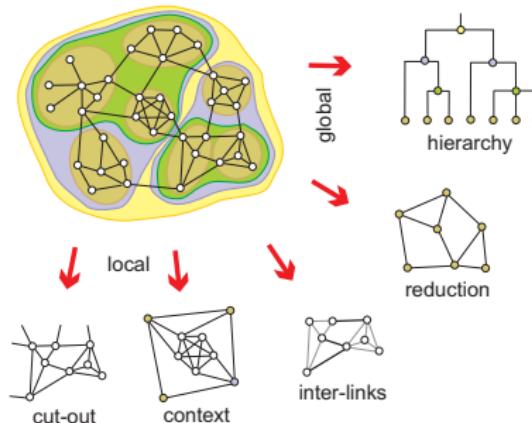

For the interactive use on large graphs already quadratic algorithms, $O(n^2)$, are too slow.

In the analysis of a *large* network (several thousands or millions of nodes, the network can be stored in computer memory) we can't display it in its totality; also there are only a few algorithms available.

To analyze a large network we can use a statistical approach or we can identify smaller (sub) networks that can be analyzed further using more sophisticated methods.

Measured properties – Input data

Erdős and Renyi defined a *random graph* as follows: every possible link is included in a graph with a given probability p .

In **Pajek** instead of probability p a more intuitive average degree is used

$$\overline{\deg} = \frac{1}{n} \sum_{v \in V} \deg(v)$$

Network/Create Random Network/Bernoulli/Poisson/Undirected/General [100] [3]

It holds $p = \frac{m}{m_{\max}}$ and, for simple graphs, also $\overline{\deg} = \frac{2m}{n}$.

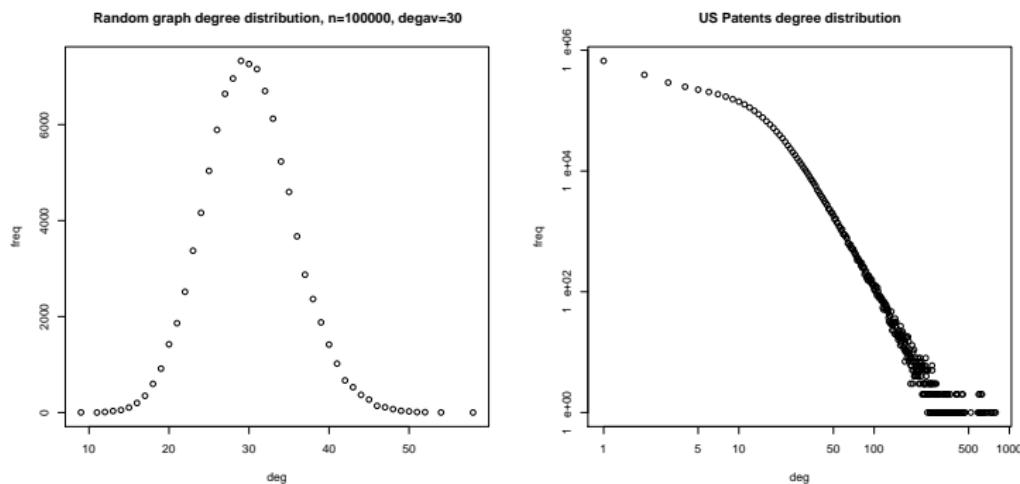

The random graph in the picture has 100 nodes and an average degree 3.

length $|s|$ of the walk s is the number of links it contains.

$$s = (j, h, l, g, e, f, h, l, e, c, b, a)$$
$$|s| = 11$$

A walk is **closed** iff its initial and terminal node coincide.

If we don't consider the direction of the links in the walk we get a **semiwalk** or **chain**.

trail – walk with all links different

path – walk with all nodes different

cycle – closed walk with all internal nodes different

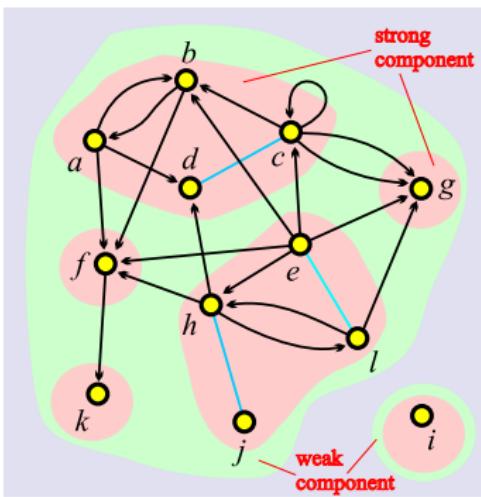

A graph is **acyclic** if it doesn't contain any cycle.

References

The standard approach to find interesting groups inside a network is based on properties/weights – they can be *measured* or *computed* from network structure.

The *node-cut* of a network $\mathbf{N} = (\mathcal{V}, \mathcal{L}, p)$, $p : \mathcal{V} \rightarrow \mathbb{R}$, at selected level t is a subnetwork $\mathbf{N}(t) = (\mathcal{V}', \mathcal{L}(\mathcal{V}'), p)$, determined by the set

$$\mathcal{V}' = \{v \in \mathcal{V} : p(v) \geq t\}$$

and $\mathcal{L}(\mathcal{V}')$ is the set of links from \mathcal{L} that have both endnodes in \mathcal{V}' .

The *link-cut* of a network $\mathbf{N} = (\mathcal{V}, \mathcal{L}, w)$, $w : \mathcal{L} \rightarrow \mathbb{R}$, at selected level t is a subnetwork $\mathbf{N}(t) = (\mathcal{V}(\mathcal{L}'), \mathcal{L}', w)$, determined by the set

$$\mathcal{L}' = \{e \in \mathcal{L} : w(e) \geq t\}$$

and $\mathcal{V}(\mathcal{L}')$ is the set of all endnodes of the links from \mathcal{L}' .

The threshold value t is determined on the basis of distribution of values of weight w or property p . Usually we are interested in cuts that are not too large, but also not trivial.

Skeletons are subnetworks in which only the most important links are preserved.

In the ***top k-neighbors skeleton*** in each node the k links with the highest weights are preserved.

Network/Create New Network/Transform/Remove/all arcs from each vertex except/ k with highest line values [k]

Let the weight w be a dissimilarity ($w' = 1/w$). The Pathfinder algorithm was proposed in eighties by Schvaneveldt [9] for simplification of weighted networks. It removes from the network all links that do not satisfy the triangle inequality – if for a link a shorter path exists connecting its endnodes then the link is removed. The obtained subnetwork is called the ***Pathfinder skeleton***.

Simple analysis using cuts

We look at the components of $\mathbf{N}(t)$. Their number and sizes depend on t . Usually there are many small components. Often we consider only components of size at least k and not exceeding K . The components of size smaller than k and not containing important nodes/links are discarded as "noninteresting"; and the components of size larger than K are cut again at some higher level.

The values of thresholds t , k and K are determined by inspecting the distribution of node/link-values and the distribution of component sizes and considering additional knowledge on the nature of network or goals of analysis.

We developed some new and efficiently computable properties/weights.

The citation network analysis started in 1964 with the paper of Garfield et al. In 1989 Hummon and Doreian proposed three indices – weights of arcs that are proportional to the number of different source-sink paths passing through the arc. We developed algorithms to efficiently compute these indices.

Main subnetwork (arc-cut at level 0.007) of the SOM (self-organizing maps) citation network (4470 nodes, 12731 arcs).

If we represent a given or computed value of nodes / links as a height of nodes / links and we immerse the network into a water up to selected level we get *islands*. Varying the level we get different islands.

We developed very efficient algorithms to determine the islands hierarchy and to list all the islands of selected sizes.

See [details](#).

... Islands

Islands are very general and efficient approach to determine the 'important' subnetworks in a given network.

We have to express the goals of our analysis with a related property of the nodes or weight of the links. Using this property we determine the islands of an appropriate size (in the interval k to K).

In large networks we can get many islands which we have to inspect individually and interpret their content.

An important property of the islands is that they identify locally important subnetworks on different levels. Therefore they detect also emerging groups.

A set of nodes $C \subseteq \mathcal{V}$ is a *regular node island* in network

$\mathbf{N} = (\mathcal{V}, \mathcal{L}, p)$, $p : \mathcal{V} \rightarrow \mathbb{R}$ iff it induces a connected subgraph and the nodes from the island are 'higher' than the neighboring nodes

$$\max_{u \in N(C)} p(u) < \min_{v \in C} p(v)$$

A set of nodes $C \subseteq \mathcal{V}$ is a *regular link island* in network

$\mathbf{N} = (\mathcal{V}, \mathcal{L}, w)$, $w : \mathcal{L} \rightarrow \mathbb{R}$ iff it induces a connected subgraph and the links inside the island are 'stronger related' among them than with the neighboring nodes – in \mathbf{N} there exists a spanning tree \mathbf{T} over C such that

$$\max_{(u,v) \in \mathcal{L}, u \notin C, v \in C} w(u, v) < \min_{(u,v) \in \mathbf{T}} w(u, v)$$

Dense groups

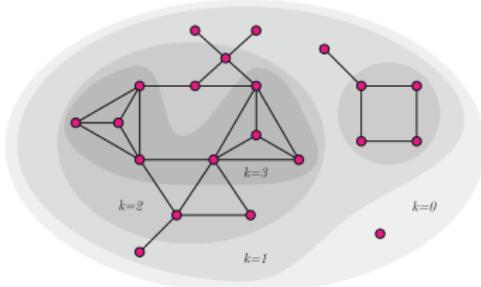

Activities in a part of network usually increase local density (number of nodes and links) in that part of network. Several notions were proposed in attempts to formally describe dense groups in graphs.

Clique of order k is a maximal complete subgraph (isomorphic to K_k), $k \geq 3$.

s-plexes, LS sets, lambda sets, cores, . . .

For all of them, except for cores, it turned out that they are "expensive" to determine.

Cores and generalized cores

The notion of core was introduced by Seidman in 1983. Let $\mathbf{G} = (\mathcal{V}, \mathcal{E})$ be a graph. A subgraph $\mathbf{H} = (W, \mathcal{E}|W)$ induced by the set W is a ***k-core*** or a ***core of order k*** iff $\forall v \in W : \deg_{\mathbf{H}}(v) \geq k$, and \mathbf{H} is a maximal subgraph with this property. The core of maximum order is also called the ***main core***.

The ***core number*** of node v is the highest order of a core that contains this node. The degree $\deg(v)$ can be: in-degree, out-degree, in-degree + out-degree, etc., determining different types of cores.

Properties of cores

From the figure, representing 0, 1, 2 and 3 core, we can see the following properties of cores:

- The cores are nested: $i < j \implies H_j \subseteq H_i$
- Cores are not necessarily connected subgraphs.

An efficient algorithm for determining the cores hierarchy is based on the following property:

If from a given graph $\mathbf{G} = (\mathcal{V}, \mathcal{E})$ we recursively delete all nodes, and edges incident with them, of degree less than k , the remaining graph is the k -core.

Generalized cores

The notion of core can be generalized to networks. Let $\mathbf{N} = (\mathcal{V}, \mathcal{E}, w)$ be a network, where $\mathbf{G} = (\mathcal{V}, \mathcal{E})$ is a graph and $w : \mathcal{E} \rightarrow \mathbb{R}$ is a function assigning values to edges. A *node property function* on \mathbf{N} , or a p -function for short, is a function $p(v, U)$, $v \in \mathcal{V}$, $U \subseteq \mathcal{V}$ with real values. Let $N_U(v) = N(v) \cap U$. Besides degrees and (corrected) clustering coefficient, here are some examples of p -functions:

$$p_S(v, U) = \sum_{u \in N_U(v)} w(v, u), \text{ where } w : \mathcal{E} \rightarrow \mathbb{R}_0^+$$

$$p_M(v, U) = \max_{u \in N_U(v)} w(v, u), \text{ where } w : \mathcal{E} \rightarrow \mathbb{R}$$

$$p_t(v, U) = \frac{|\mathcal{L}(U) \cap \mathcal{L}(K(N^+(v)))|}{|\mathcal{L}(K(N^+(v)))|}$$

$$p_k(v, U) = \text{number of cycles of length } k \text{ through node } v \text{ in } (U, \mathcal{E}|U)$$

The subgraph $\mathbf{H} = (C, \mathcal{E}|C)$ induced by the set $C \subseteq \mathcal{V}$ is a *p -core at level $t \in \mathbb{R}$* iff $\forall v \in C : t \leq p(v, C)$ and C is a maximal such set.

Additional p -functions

relative density

$$p_\gamma(v, \mathcal{C}) = \frac{\deg(v, \mathcal{C})}{\max_{u \in N(v)} \deg(u)}, \text{ if } \deg(v) > 0; 0, \text{ otherwise}$$

diversity

$$p_\delta(v, \mathcal{C}) = \max_{u \in N^+(v, \mathcal{C})} \deg(u) - \min_{u \in N^+(v, \mathcal{C})} \deg(u)$$

average weight

$$p_a(v, \mathcal{C}) = \frac{1}{|N(v, \mathcal{C})|} \sum_{u \in N(v, \mathcal{C})} w(v, u), \text{ if } N(v, \mathcal{C}) \neq \emptyset; 0, \text{ otherwise}$$

Generalized cores algorithms

The function p is *monotone* iff it has the property

$$C_1 \subset C_2 \Rightarrow \forall v \in \mathcal{V} : (p(v, C_1) \leq p(v, C_2))$$

The degrees and the functions p_S , p_M and p_k are monotone. For a monotone function the p -core at level t can be determined, as in the ordinary case, by successively deleting nodes with value of p lower than t ; and the cores on different levels are nested

$$t_1 < t_2 \Rightarrow \mathbf{H}_{t_2} \subseteq \mathbf{H}_{t_1}$$

The p -function is *local* iff $p(v, U) = p(v, N_U(v))$.

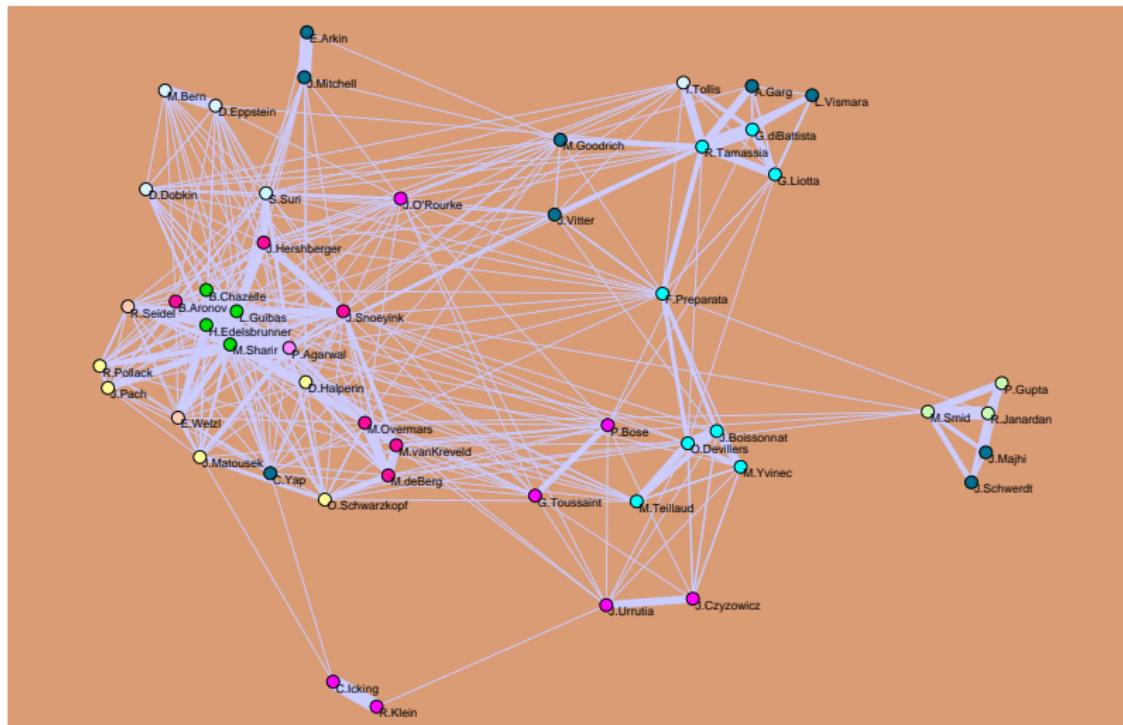

The degrees, p_S and p_M are local; but p_k is **not** local for $k \geq 4$. For a local p -function an $O(m \max(\Delta, \log n))$ algorithm for determining the p -core levels exists, assuming that $p(v, N_C(v))$ can be computed in $O(\deg_C(v))$.

Clustering and blockmodeling

For clustering the nodes, we use the normalized matrices. When computing the dissimilarity $d[u, v]$ between nodes u and v in a weighted network \mathbf{C} it is important to use the corrected dissimilarities. Here we compare the entry $c[u, t]$ with the entry $c[v, t]$ for t different from u or v , and the entry $c[u, v]$ with the entry $c[v, u]$, and the entry $c[u, u]$ with the entry $c[v, v]$. We selected the *corrected Euclidean distance* (Doreian et al., 2005, p. 181)

$$d_e[u, v] = \sqrt{(c[u, v] - c[v, u])^2 + (c[u, u] - c[v, v])^2 + \sum_{t: t \neq u \wedge t \neq v} (c[u, t] - c[v, t])^2}$$

subnetworks

References

From the site <https://datausa.io/profile/geo/united-states/> we obtained the data about US states in 2016 for the following variables: crime – homicide deaths, violent – violent crimes, smoking – adult smoking prevalence, drinking – excessive drinking prevalence, diabetes – diabetes prevalence, opioid – opioid overdose death rate, and income – median household income.

In his book *The Stanford GraphBase* D.E. Knuth provided a description of neighboring relation for the contiguous part of USA `contiguous-usa.dat` (without Alaska and Hawaii). Because of missing data we removed also Washington DC.
